9. Circuit Description

Differences with the VM8 system : In respect to the field calls of the VM8 system (See Training Manual VM8 service code 4822 727 20401), the VM6 system is improved on several points like:

- The use of other components in the camera interface and the deflection part
- An other transformer in the power supply
- Several software improvements
- For the POS monitor an extra Slave twisted pair interface
- The Slave monitor has a Twisted pair input
- The EHT is increased to improve picture quality
- A system on/off switch at the back of the monitor.

The deflection part differs (electronically) of that of the VM8 system. A new deflection control IC is introduced (TEA 2037A) which generates not only the horizontal and vertical drive but also the Vertical feedback pulses (VFB).

The DC level of the input stage (pin 15, 7405) is determined by 3402. The value of 3402 is chosen in such a way that only the synchronisation pulses of the video signal is fed into the input stage of 7405. After the input stage these pulses are fed in the phase detector and the frame sync. separator. The line oscillator (which is free running at approx. 14,6 kHz) will lock itself (PLL) to the line pulses originating from the incoming video. The line output stage is capable of driving the line output transistor 7530 directly. Via 3425 the phase of the line output stage is monitored. When the line output is getting out of phase, the phase detector will adjust its output, so the line output will get in phase again. As the VCC1 voltage (9,8 Volt) used for the horizontal and vertical oscillators as a reference, (is precise and stable) (using 2423 and 3423 as 1% components) it is not necessary to have a line oscillator adjustment. The line output stage of 7405 has an open collector therefore 3440, 3411 and 3409 are added. 3431, 6430 and 6431 are used to discharge 2490 during the down going flank of pin 14 of 7405.

The frame oscillator is locked to the vertical pulses. These pulses are fed into the vertical power stage, which is capable to drive the vertical deflection coil directly. Via feedback 3414, 3417 and 3413 the amplitude of the vertical drive is obtained. To prevent seeing vertical fly-back lines, the VFB is generated to suppress the video output when fly-back lines are present. Therefore VFB is no feedback but an outgoing signal !! The fly-back generator is essentially a switch which is closed when a Vertical Feed-Back pulse (VFB) is needed.

- During the scan the fly-back generator switch is open so 2410 is charged to approx. +14V via 6432.
- During the fly-back the fly-back generator switch is closed so pin 3 of 7406 is +14V. As 2410 is still charged to +14V, pin 7 of 7406 becomes approx. +28V at the beginning of the fly-back.
- During the fly-back the current through the deflection coil must quickly come to "0". Due to the inductive reaction of the deflection coil more energy is needed (therefor the +28V is used)

Power save circuitry (schematic A1): In the POS and Retail the STAND-BY button is a pulse switch. This pulse is used by the μ P to switch off the +10S and +24S using 10S-ENABLE (pin 15, 7875). In this way the line output stage the deflection part and the filament voltage are switched off. In the Slave monitor however no μ P is used, therefore 9804 and 9881 are added and a make switch is used for the STAND-BY. In stand-by the switch is open and via 9881 and 7943 the +10S and +24S are switched off. When the Slave is turned off (rear side) the +24V and +24S are switched off. As the +24V is switched off, the +10S is switched off too via 6916 and 9804
